Medical Machining: Cutting Tool Manufacturers Offer Insights, Advice for Success

Kip Hanson | Nov 17, 2020

Medical implant manufacturing is poised for significant growth as techniques and materials continually improve. Here, experts offer valuable insights into the materials, methods and machine tools used in medical machining.

Each industrial sector faces unique challenges, but medical machining presents some of the biggest. Close tolerances, complex geometries and meticulous traceability—these are just a few of the hurdles that medical shops must leap if they're to compete in this demanding field.

Fortunately, plenty of knowledgeable people are willing to share application advice, starting with the experts cited here.

Consider materials. Next to aerospace with its high-temp superalloys, the metals used to make medical components come in a close second in terms of poor machinability. Dan Doiron, milling product manager at Emuge Corp., explains that cobalt chrome bar stock and castings, for example, are commonly used to make the femoral (upper) component of a knee implant, with titanium serving as the tibial tray below. Stainless steels such as 17-4 PH are also quite common in medical applications, such as the surgical alignment and clamping tools used during implant installation.

All are tough to machine, and all require material-specific cutting tools for the greatest productivity.

"Regardless of what you're making, you need the best equipment you can afford if you're to be competitive."

Jacob Rak
KYOCERA SGS

"Whatever the alloy, I always recommend that customers refer to our website or catalog when selecting cutting tools," he says. "We have a wide range of geometries intended for various medical materials, as well as coatings that aid in maintaining longevity and provide optimal tool life."

Riding the Additive Express

Additive manufacturing, more commonly known as 3D printing, is big in the medical world, and only getting bigger. And even though the technology has long promised to eliminate machining operations, cutting tool manufacturers are responding to the call for additive manufacturing-specific geometries.

Emuge's milling product manager Dan Doiron, for example, points to the increased use of hybrid additive lathes and machining centers, operations that call for special necked-down cutters to reach past previously printed part layers.

"Hybrid additive machining facilitates new design possibilities, such as a one-piece design of a component, complex internal structures or material properties," he says.

And Chris Dravis, regional manager at OSG USA Inc., says the company is now carrying tools specific to the removal of 3D-printed materials.

"The primary limitations with additive are twofold," he says. "The first is that 3D printers aren't very accurate, at least relative to conventional machine tools. Secondly, the parts coming off these machines are often quite complex."

In either case, there's a need for high-quality cutting tools that are able to: a) reach deep into 3D-printed parts; and b) take light cuts with minimal tool pressure. According to Dravis, OSG is delivering on both counts.

"Quite often, we'll recommend an end mill with a large corner radius, very high helix angle, and six or even eight flutes," he says. "This allows you to take advantage of the fact that you're not removing a lot of material. You can use minimal radial engagement and high feed rates but still reduce tool pressures."

Derek Nading, applications engineer for M.A. Ford Mfg. Co. Inc., agrees, noting that custom cutting tools are also quite common in the medical sector.

"We make a lot of special reamers and step drills for medical use, where a shop might want to complete two or more part features in one operation," he says. "And barrel cutters, also known as circle segment tools, are becoming more popular as well, used primarily for accelerated finishing of hip replacements and other complex implants."

KYOCERA SGS research and development engineer Jake Rutherford warns that cutting tool coatings might be forbidden in particular medical applications.

"That's why we offer our tools coated or uncoated," he says. "I've been to shops where it was difficult or even impossible to validate a process due to concerns there would be microscopic elements of the coating left behind on the component, which could, in turn, leach into the human body."

A Methodical Approach

Note that last term: process validation. Like those making critical aerospace components, medical shops must often submit their machining processes for customer approval, and once validated, are frozen in place. Any deviations from these processes after the fact require additional approvals, making continuous improvement cumbersome at best.

One moral to this story is that medical shops should bring in cutting tool experts early during the process development cycle. This helps ensure that they select the best tools, determine the most efficient toolpaths possible, and avoid going back to the customer for post-validation changes. In other cases, however, doing so is well worth the effort, especially on jobs that have been running for years, or where the shop is otherwise behind the times in terms of cutting tool technology.

One case in point comes from OSG USA Inc., where district manager Dustin Loschiavo works closely with a medical shop in Michigan.

"We and some of our engineers visited their facility last October after they agreed to partner with us," Loschiavo says. "We evaluated their processes, looked at their machine tools and workholding, and delivered solutions that would save them more than \$300,000 annually on just four components."

OSG regional manager Chris Dravis isn't surprised. "In this particular case, they were using 10-year-old cutting tool technology," he says. "By moving them over to tools designed for modern toolpaths, they were able to greatly increase cutter engagement, significantly improving tool life and metal removal rates alike. Granted, there are internal costs associated with them going back to the customer and taking the time to re-validate the processes, but in this and many other instances, it's well worth it."

OSG district manager Aaron Kwapniewski agrees, noting that there are currently 6,500-plus domestic medical device manufacturers, and there continues to be a large demand on all of them to reduce lead times and trim prices. "If they're not taking advantage of the latest and greatest tooling, they're leaving money on the table and putting themselves at risk, perhaps, of losing business to other competitors," he notes.

Dan Doiron of Emuge has had similar experiences. He says that strict protocols to ensure the consistency of implant manufacturing exist. Traceability is critical, requiring that businesses document what batch of material, which machine tool and even the type of cutting fluid they use for a specific part. "Changing to a different brand of cutting tool is generally not allowed without a review as to why that change is necessary," he says. "Despite this, it's often a necessary pain if shops are to stay competitive."

Many of these parts are small, easily falling into micromachining territory. KYOCERA SGS applications engineer Jacob Rak listed off a handful of smaller medical components, from stents and bone screws to parts for heart pumps and respiration monitoring sensors. Swiss-style CNC lathes have long been used to machine many of these, with 5-axis machining centers more common for implant manufacturing.

"Medical parts often have unique geometries and are made from difficult materials, so it's demanding work," he says. "Regardless of what you're making, you need the best equipment you can afford if you're to be competitive."

Raise the Toolholding Bar

Whatever the machine tool, whatever the part, tight tolerances and extremely fine surface finishes mean that manufacturers must also raise the bar on their toolholding. The need for minimal runout and maximum rigidity demands shrink-fit or hydraulic chuck use wherever possible. Tiny cutters might

require investment in speeder heads to achieve the correct operating speed, and filtered, high-pressure coolant is a must. And always follow the cutting tool manufacturer's recommendations—most agree that machinists are often afraid to push the tools as hard as they should, which usually leads to premature tool wear.

Some are also afraid to invest in high-quality tools or ask for help selecting them. That's according to Doiron, who noted that Emuge—like most cutting tool manufacturers—performs scientific testing of carbide grades, coatings, rake and helix angles, end gashing and more. Yes, all of these companies want to sell tools, but the best way to do that is to provide their customers with successful outcomes.

"Investment in the optimal tool for an application can mean the difference between running lights-out, or even between profit and loss," he notes. "That's been my experience, both as an end user and here working at Emuge."
